

a Warming stops helping once a province passes the thermal envelope

Marginal effect of warming with 95% CI. Rug: the observed distribution.
Interaction HR 0.906 (0.838-0.980), P = 0.014.

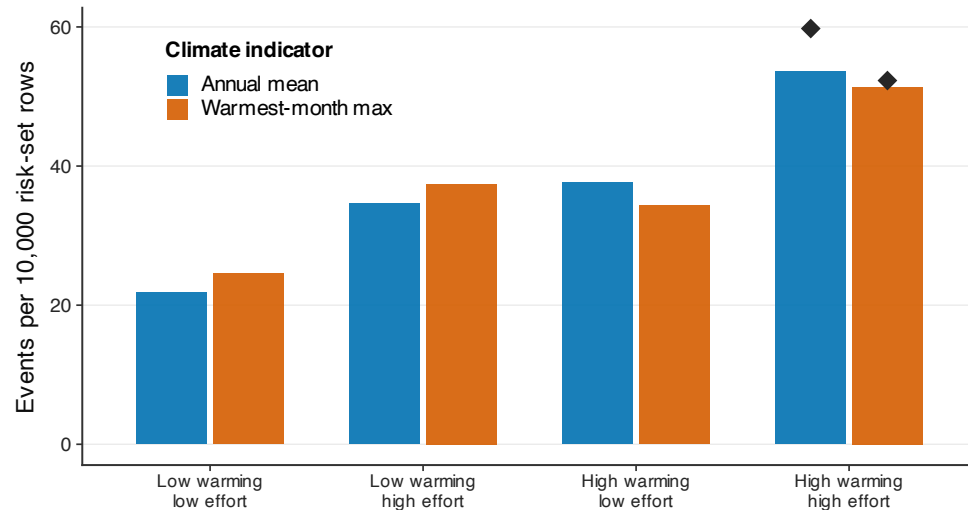

b Candidate provinces are already on the warm side

Which is why a metric built on distance from the niche centre cannot work

c The interaction is visible before any model is fitted

Diamonds: the rate expected from the two margins alone.
Annual mean falls 10% short of it (sub-multiplicative = negative interaction);
the warmest-month proxy falls only 2% short, that is, essentially multiplicative.

d Both interactions hold across candidate pools and effort proxies

Filled points P < 0.05. Sample sizes differ across settings, so coefficients are compared but AIC is not.
